The analysis of uncertainty of very large dynamical systems over a wide range of frequency is a significant challenge. In this paper a new reduced-order computational approach for very large damped stochastic linear dynamical systems is proposed. The approach is based on transformation and reduction of the stochastic system in the modal domain. A Wishart random matrix distribution is considered for the eigen-solution of the reduced-order system. The identification of the parameters of the Wishart random model has been discussed. The newly proposed approach is compared with the existing random matrix models using numerical case studies. Results from the new approach have been validated using an experiment on a vibrating plate with randomly attached spring-mass oscillators. One hundred nominally identical samples have been physically created and individually tested within a laboratory framework. A simple step-by-step simulation method for implementing the new computational approach in conjunction with general purpose finite element software has been outlined. The method is applied to an aircraft wing problem with uncertainty to illustrate the generality, portability and the non-intrusive nature of the proposed approach.

1. Introduction

The analysis of uncertainty of very large dynamical systems over a wide range of frequency is a significant challenge [1,2]. In this paper a new reduced-order computational approach for damped stochastic linear dynamical systems is proposed using Wishart random matrix distribution. The use of random matrices to model uncertainty was proposed by Soize [3–5] and subsequently researched by others [6–10]. Although the validity of the Wishart random matrix is proven in various structural dynamical problems over the past decade, the computational methods till date relies on the direct Monte Carlo Simulation. It is therefore crucial to develop efficient simulation method to consider real-life problems with very large matrix sizes. The equation of motion of a damped n-degree-of-freedom linear dynamic system can be expressed as

\[
M\ddot{q}(t) + C\dot{q}(t) + Kq(t) = f(t)
\]

where \(f(t)\in \mathbb{R}^n\) is the forcing vector, \(q(t)\in \mathbb{R}^n\) is the response vector and \(M\in \mathbb{R}^{n\times n}\), \(C\in \mathbb{R}^{n\times n}\) and \(K\in \mathbb{R}^{n\times n}\) are the mass, damping and stiffness matrices, respectively. In order to completely quantify the uncertainties associated with system (1) we need to obtain the probability density functions of the random matrices \(M\), \(C\) and \(K\). Using the parametric approach, such as the stochastic finite element method [11], one usually obtains a problem specific covariance structure for the elements of system matrices. The nonparametric approach [3–5] on the other hand results in a central Wishart distribution (or more generally, the matrix variate Gamma distribution [12]) for the system matrices. Wishart matrix with properly selected parameters can be used for systems with both parametric uncertainty and nonparametric uncertainty [see for example [13–16]].

The aim of this paper is to investigate an efficient simulation method to obtain frequency response function (FRF) statistics with Wishart matrices. The approach is based on transformation and reduction of the stochastic system in the modal domain. Recently in the context of parametric uncertainty, Pichler et al. [17] proposed a meta-model approach in the modal domain for the calculation of frequency response statistics. Here, a Wishart random matrix distribution is considered for the eigensolution of the reduced-order system. The identification of the parameters of the Wishart random model has been discussed. The newly proposed approach is compared with the existing random matrix models using numerical case studies. Results from the new approach have been validated using an experiment on a vibrating plate with randomly attached spring-mass oscillators. One hundred nominally identical samples have been physically created and individually tested within a laboratory framework. A simple step-by-step simulation method for implementing the new computational approach in conjunction with general purpose finite element...
software has been outlined. The method is applied to an aircraft wing problem with uncertainty to illustrate the generality, portability and the non-intrusive nature of the proposed approach.

2. The generalized Wishart random matrix model

The generalized Wishart random matrix model was recently introduced by Adhikari [18]. Here we briefly review the necessary details. Suppose the mass and stiffness matrices corresponding to the dynamic parameter associated with the stiffness matrix is defined as a measure of uncertainty in the system and it is similar to the normalized standard deviation of a matrix. For example, the dispersion parameter associated with the mass matrix can be defined in a similar way.

\[
\delta^2_m = \frac{\mathbb{E}\left\{ |K - K_0|^2 \right\}}{\|K_0\|^2}
\]

where \(\|\cdot\|\) denotes the Frobenius norm of a matrix, and the symbol \(\mathbb{E}\{\ldots\}\) denotes the operation of averaging with respect to the corresponding probability distribution. The dispersion parameter \(\delta_m\) associated with the mass matrix can be defined in a similar way. The dispersion parameters \(\delta_m\) and \(\delta_k\) can be obtained using the stochastic finite element method or experimental measurements [6].

Given the dispersion parameters \(\delta_m\) and \(\delta_k\) and the baseline mass and stiffness matrices \(M_0\) and \(K_0\), the parameters for the random matrices \(M\) and \(K\) can be obtained in closed-form. Various parameter selection options have been investigated [9] and the optimal parameters can be obtained via closed-form expressions using optimisation approaches.

It is well known that the dynamic response of a proportionally damped stochastic system is characterized by the eigensolutions of the dynamic matrix

\[
H = M^{-1/2}KM^{-1/2}
\]

In general, when \(K\) and \(M\) are Wishart matrices, the matrix \(H\) is not a Wishart matrix (see e.g. [12] for its distribution). However, Adhikari [18] investigated the possibility of \(H\) itself being a Wishart matrix. Since \(H\) is a positive definite matrix, a Wishart matrix can be fitted using the maximum entropy principle [3, 4] just like the mass and stiffness matrices, provided the dispersion parameter of a Wishart matrix and the dispersion parameter of the random matrices \(M\) and \(K\) can be obtained in closed-form. Several quantitative description of stochastic dynamics. The detailed derivation of such generalized Wishart matrix and its numerical and experimental validation can be found in [18]. It was shown that

\[
H \sim W_{s}(\rho, \Sigma)
\]

where \(W_{s}(\rho, \Sigma)\) denotes a \(n\) dimensional Wishart matrix. The parameters \(\rho\) and \(\Sigma\) can be obtained from the available data regarding the system, namely \(M_0\), \(K_0\), \(\delta_m\), and \(\delta_k\). Dynamical responses obtained using this generalized Wishart matrix have been validated [18] against the stochastic finite element method, full Wishart matrices and experimental results. Here we take this model to obtain the reduced random matrix. The main focus of the present paper is to develop an efficient reduced computational approach for large dynamical systems. The proposed approach is integrated with a commercial finite element software by exploiting its non-intrusive nature.

3. The reduced Wishart matrix approach

Assuming all the initial conditions are zero and taking the Laplace transform of the equation of motion (1) we have

\[
[s^2M + sC + JK(q(s) = f(s)]
\]

where \((\cdot)\) denotes the Laplace transform of the respective quantities. The aim here is to obtain the statistical properties of \(q(s) \in \mathbb{C}^m\) when the system matrices are random matrices. The undamped eigenvalue problem is given by

\[
K\phi_j = \omega^2_jM\phi_j, \quad j = 1, 2, \ldots, n
\]

where \(\omega^2_j\) and \(\phi_j\) are respectively the eigenvalues and mass-normalized eigenvectors of the system.

A high resolution model of a dynamical system can easily have several million degrees-of-freedom (that is \(n\)). On the other hand, it may be only few hundreds or thousands modes are necessary for the calculation of the dynamic response within the frequency range considered. Suppose the number of modes to be retained is \(m\). In general \(m \ll n\). The selection of reduced modes depends on the frequency of excitation. If the maximum frequency of excitation is \(\omega_{\text{max}}\), then \(m\) should be such that at least \(\omega_m > \omega_{\text{max}}\). Several excellent references exist [19] on the selection of modal order for dynamic problems.

We form the truncated undamped modal matrices

\[
\Omega = \text{diag}(\omega_1, \omega_2, \ldots, \omega_m) \in \mathbb{R}^{m \times m} \quad \text{and} \quad \Phi = [\phi_1, \phi_2, \ldots, \phi_m] \in \mathbb{R}^{n \times m}
\]

so that

\[
\Phi^T\Phi = \Omega^2 \quad \text{and} \quad \Phi^T\Phi = I_m
\]

where \(I_m\) is a \(m\)-dimensional identity matrix. Using these, Eq. (5) can be transformed into the modal coordinates as

\[
[s^2I_m + sC + \Omega^2]q = f
\]

where and \((\ast)\) denotes the quantities in the reduced modal coordinates:

\[
C = \Phi^T C \Phi \in \mathbb{R}^{m \times m}, \quad q = \Phi q^\ast \quad \text{and} \quad f = \Phi f^\ast
\]

For simplicity let us assume that the system is proportionally damped with deterministic modal damping factors \(\zeta_1, \zeta_2, \ldots, \zeta_m\). Therefore, when we consider random systems, the matrix of eigenvalues \(\Omega^2\) in Eq. (9) will be a random matrix of dimension \(m\). Suppose this random matrix is denoted by \(\Xi \in \mathbb{R}^{m \times m}\):

\[
\Omega^2 \sim \Xi
\]

From the definition of \(\Phi\) in Eq. (3) it is clear that \(\Xi\) is a Wishart matrix and the dispersion parameter of \(\Xi\) and \(H\) are the same. Since \(\Xi\) is a symmetric and positive definite matrix, it can be diagonalized by an orthogonal matrix \(\Psi\), such that

\[
\Psi^T \Xi \Psi = \Omega^2
\]

Here the subscript \(r\) denotes the random nature of the eigenvalues and eigenvectors of the random matrix \(\Xi\). Recalling that \(\Phi^T \Psi = I_m\), from Eq. (9) we obtain

\[
q^\ast = \Psi^T[q^\ast I_m + 2\zeta \Omega + \Omega^2]^{-1}f^\ast
\]

where

\[
\zeta = \text{diag}(\zeta_1, \zeta_2, \ldots, \zeta_m) \in \mathbb{R}^{m \times m}
\]
The response in the original coordinate can be obtained as

\[ \ddot{q}(s) = \Phi \Phi^T \ddot{q}(s) = \Phi \Phi^T [s^2 I_n + 2s(\Omega + \Omega^T)]^{-1} (\Phi \Phi^T) \tilde{f}(s) \]

\[ = \sum_{j=1}^{m} \lambda_j^2 f_j(s) \]

(16)

Here

\[ \Omega = \text{diag}(\omega_1, \omega_2, \ldots, \omega_n) \]  
(17)

and \[ \Phi \Phi^T = [\Phi_1, \Phi_2, \ldots, \Phi_m] \]  
(18)

are respectively the matrices containing random eigenvalues and eigenvectors of the system. The Frequency Response Function (FRF) of the system can be obtained by substituting \( s = i\omega \) in Eq. (16). The computational methodology relies on the undamped random eigenvalue problems. Therefore, if a perturbation type of approach is adopted (for example [20]), then the method can be extended to general nonproportional or nonviscously [21] damped systems with light damping. In the next section we summarize the Monte Carlo Simulation (MCS) based computational approach arising from this analysis.

4. Summary of the computational approach

A step-by-step method for implementing the new computational approach in conjunction with any general purpose finite element software is given below:

1. Form the deterministic mass and stiffness matrices \( M_0 \) and \( K_0 \) using the standard finite element method and the modal damping factors \( \zeta \). Select the number of modes \( m \). The number of modes to be retained, \( m \) should be selected based on the frequency of excitation.

2. Solve the deterministic undamped eigenvalue problem

\[ K_0 \phi_j = \omega_j^2 M_0 \phi_j, \quad j = 1, 2, \ldots, m \]

(19)

and create the matrix

\[ \Phi_0 = [\phi_{01}, \phi_{02}, \ldots, \phi_{0n}] \in \mathbb{R}^{n \times m} \]  
(20)

Calculate the ratio

\[ \beta_M = \left( \sum_{j=1}^{m} \omega_j^2 \right) / \left( \sum_{j=1}^{m} \omega_0^2 \right) \]  
(21)

3. Obtain the dispersion parameters \( \delta_M \) and \( \delta_k \) corresponding to the mass and stiffness matrices. This can be obtained from physical or computer experiments.

4. Obtain the dispersion parameter of the generalized Wishart matrix \( \mathbf{H} \) in Eq. (3) as [18]

\[ \delta_H = \frac{\left( \rho_M^2 + (p_k - 2 - 2n)p_k + (-n - 1)p_k + n^2 + 1 + 2n \right)\beta_M}{p_k(-p_M + n)(-p_M + n + 3)} + \frac{\rho_K^2 + (p_k - 2n)p_k + (1 - n)p_k - 1 + n^2}{p_k(-p_M + n)(-p_M + n + 3)} \]

where

\[ p_M = \frac{1}{\delta_M} \left\{ 1 + \text{Trace}(M_0) \right\}^2 / \text{Trace}(M_0^2) \]  
(23)

and \[ p_K = \frac{1}{\delta_K} \left\{ 1 + \text{Trace}(K_0) \right\}^2 / \text{Trace}(K_0^2) \]  
(24)

5. Calculate the parameters

\[ \theta = \frac{(1 + \rho_M)}{\delta_M} \left( m + 1 \right) \quad \text{and} \quad p = [m + 1 + \theta] \]  
(25)

where \( p \) is approximated to the nearest integer of \( m + 1 + \theta \).

6. Create an \( m \times p \) matrix \( \mathbf{Y} \) such that

\[ Y_{ij} = \omega_0 \sqrt{1 - \gamma^2}; \quad i = 1, 2, \ldots, m; \quad j = 1, 2, \ldots, p \]

(26)

where \( \gamma \) are independent and identically distributed (i.i.d.) Gaussian random numbers with zero mean and unit standard deviation.

7. Simulate the \( m \times m \) Wishart random matrix

\[ \Xi = \mathbf{Y} \mathbf{Y}^T \]

(27)

or \[ \Xi_{ij} = \frac{\omega_0}{\gamma} \sum_{k=1}^{p} \gamma_i \gamma_k; \quad i = 1, 2, \ldots, m; \quad j = 1, 2, \ldots, m \]

(28)

Since \( \Xi \) is symmetric, only the upper or lower triangular part need to be simulated.

8. Solve the symmetric eigenvalue problem \( (\Omega_0 \mathbf{V}_0, \mathbf{V}_0) \in \mathbb{R}^{m \times m} \) for every sample

\[ \Xi \mathbf{V}_0 = \Omega_0^2 \mathbf{V}_0 \]  
(29)

and obtain the random eigenvector matrix

\[ \mathbf{X}_0 = \Phi_0 \mathbf{V}_0 = [\mathbf{x}_{10}, \mathbf{x}_{20}, \ldots, \mathbf{x}_{n0}] \in \mathbb{R}^{n \times m} \]

(30)

The samples of the response in the time domain can also be obtained from the random eigensolutions as

\[ q(t) = \sum_{j=1}^{m} a_j(t) \mathbf{x}_j, \quad \text{where} \quad a_j(t) = \frac{1}{\omega_j} \int_0^t \mathbf{x}_j^T(t) e^{-(\omega_j t - \tau)} \sin(\omega_j(t - \tau)) d\tau \]

(31)

The above procedure can be implemented very easily. When one implements this approach in conjunction with a general purpose commercial finite element software, the commercial software needs to be accessed only once to obtain the mean matrices \( M_0 \) and \( K_0 \) and solve the corresponding deterministic eigenvalue problem. This computational procedure proposed here is therefore ‘non-intrusive’.

The main computationally intensive part of a random matrix based approach is the generation of the random matrices (by matrix multiplication in Eq. (27)) and solution of the eigenvalue problem. Both the matrix multiplication and the matrix eigenvalue problem scales approximately cubically with the dimension [22]. Therefore, the computational cost of the approach grows \( \approx O(m^3) \) compared to \( \approx O(n^2) \) for the full Wishart matrix based approach. Since \( m < n \), the reduced approach is expected to be computationally efficient.

5. Numerical and experimental validation

5.1. Plate with randomly inhomogeneous material properties: numerical study

A rectangular cantilever steel plate is considered to illustrate the application of the proposed generalized Wishart random matrices in probabilistic structural dynamics. The deterministic properties are assumed to be \( E = 200 \times 10^3 \, \text{N/m}^2, \quad \mu = 0.3 \) and \( \rho = \ldots \)
randomly inhomogeneous material properties.

Comparison of the mean of the amplitude obtained using the direct stochastic finite element simulation and three Wishart matrix approaches for the plate with $f_{\text{r}} = 7860 \text{ kg/m}^3, L_x = 0.998 \text{ m}, L_y = 0.59 \text{ m}$. These values correspond to the experimental study discussed in the next section. The following three methods are explicitly compared to gain further understanding of the proposed reduced-order method:

- **Method 1 – Mass and stiffness matrices are fully correlated Wishart matrices:** For this case $M \sim W_{n}(p, \Sigma_{M}), K \sim W_{n}(p, \Sigma_{K})$ with $E[M] = M_0$ and $E[K] = K_0$. This is similar to the approach proposed by [3,4] (the original approach requires the simulation of Gamma matrices [12] which is computationally more expensive). This method requires the simulation of two $n \times n$ fully correlated Wishart matrices and the solution of a $n \times n$ generalized eigenvalue problem with two fully populated matrices. The computational cost of this approach is $\approx O(n^3)$.

- **Method 2 – Generalized Wishart Matrix [18]:** For this case $\mathcal{E} \sim W_{n}(p, \Sigma_{M}/\theta)$ with $E[\mathcal{E}] = \Sigma_{M}^{-1}$ and $\delta_{\theta} = \delta_{\mu}$. This requires the simulation of one $n \times n$ uncorrelated Wishart matrix and the solution of an $n \times n$ standard eigenvalue problem. The computational cost of this approach is $\approx O(n^3)$.

- **Method 3 – Reduced diagonal Wishart Matrix:** For this case $\mathcal{E} \sim W_{n}(p, \Omega_{M}/\theta)$ with $E[\mathcal{E}] = \Sigma_{M}^{-1}$ and $\delta_{\theta} = \delta_{\mu}$. We used tilde to differentiate with the previous case. This requires the simulation of one $m \times m$ uncorrelated Wishart matrix and the solution of a $m \times m$ standard eigenvalue problem. For large complex systems $m$ can be significantly smaller than $n$. The computational cost of this approach is $\approx O(m^3)$.

The methods are listed in the decreasing order of computational cost. Here we aim to verify their accuracy using numerical and computational examples. It is assumed that the Young’s modulus, Poisson’s ratio, mass density and thickness are correlated homogenous Gaussian random fields. For example the Young’s modulus can be considered as $E(x) = E(1 + \epsilon_j f_j(x))$ where $f_j(x)$ is the random field and $\epsilon_j$ is the standard deviation. The standard deviation of the four random fields are considered to be $10, 10, 8$ and $12$ percent of the mean values respectively. An exponential correlation function with correlation length 0.2 times the lengths in each direction has been considered. Each of the random fields are simulated by expanding them using the Karhunen–Loève expansion [11] involving uncorrelated standard normal variables as

$$f(x) = \epsilon \sum_{j=1}^{M} \hat{\phi}_j \sqrt{j} \phi_j(x)$$  \hspace{1cm} (32)

Here $\phi_j(x)$ is the eigenfunction, $\phi_j$ are independent and identically distribute Gaussian random variables and $M$ is the number of terms used in the expansion. For the exponential autocorrelation function, the expressions of $\lambda_j$ and $\phi_j(x)$ given in Reference [11] have been used. System matrices are simulated using the values of the system properties generated via the Karhunen–Loève expansion. A 10,000-sample Monte Carlo Simulation is performed to obtain the frequency response functions (FRFs) of the system.

We want to verify how the results from the proposed reduced Wishart matrix approach correspond with the direct stochastic finite element Monte Carlo Simulation results. We are also interested to understand whether significant accuracy is lost when comparing the simplified method with the original approach involving two fully correlated Wishart matrices [3–5]. The discretized model has 4650 degrees-of-freedom so that $n = 4650$. In the reduced approach only 80 modes have been used, that is $m = 80$. The baseline model has 77 modes up to 1 kHz frequency considered as the numerical results. The number of modes used here are therefore sufficiently higher and expected to produce physically meaningful results. From the simulated random mass and stiffness matrices we obtain $\delta_{\mu} = 0.1133$ and $\delta_{\sigma} = 0.2916$. Since $\%$ constant modal damping factor is assumed for all the modes, $\delta_{\mu} = 0$. The only uncertainty related information used in the random matrix approach are the values of $\delta_{\mu}$ and $\delta_{\sigma}$. The information regarding which element property functions are random fields, nature of these random fields (correlation structure, Gaussian or non-Gaussian) and the amount of randomness are not used in the proposed approach. The predicted mean of the amplitude using the direct stochastic finite element simulation and three Wishart matrix approaches are compared in Fig. 1 for the driving-point-FRF and a cross FRF. The predicted standard deviation of the amplitude using the direct stochastic finite element simulation and three Wishart matrix approaches are compared in Fig. 2 for the driving-point-FRF and the cross FRF. Among the three Wishart matrix approaches discussed here, the reduced diagonal Wishart matrix approach produces accurate results across the frequency range. A random eigenvalue problem involving a single $80 \times 80$ is solved for the reduced approach. For the generalized Wishart approach, a random eigenvalue problem involving a single $4650 \times 4650$ is solved for every sample. When the mass and stiffness matrices are fully correlated Wishart matrices, a generalized eigenvalue problem involving two $4650 \times 4650$ matrices are solved for every
sample. This example numerically validated the reduced random matrix approach proposed in the paper.

5.2. Plate with randomly attached spring-mass oscillators: experimental study

We consider the dynamics of a steel cantilever plate with homogeneous geometric (i.e. uniform thickness) and constitutive properties (i.e. uniform Young’s modulus and Poisson’s ratio) described in the previous section. This uniform plate defines (as considered in the numerical studies in the previous section) the baseline system. The baseline model is perturbed by a set of spring-mass oscillators with different natural frequencies and attached randomly along the plate. The details of this experiment have been described in [23]. Here we give a very brief overview. The overall arrangement of the test rig is shown in Fig. 3.

The plate is clamped along one edge using a clamping device. In total ten oscillators are used to simulate uncertainty in the system (see Fig. 3(b)). The spring is glue-welded with a magnet at the top and a mass at the bottom. The magnet at the top of the assembly helps to attach the oscillators at the bottom of the plate repeatedly without much difficulty. The stiffness of the ten springs used in the experiment are 16.800, 09.100, 17.030, 24.000, 15.670, 22.880, 17.030, 22.880, 21.360 and 19.800 kN/m. The oscillating mass of each of the 10 oscillators is 121.4 g. Therefore the total oscillating mass is 1.214 kg, which is 9.8% of the mass of the plate. The natural frequencies of the ten oscillators are obtained as 59.206, 43.574, 59.609, 70.764, 57.180, 69.094, 59.609, 69.094, 66.759 and 64.275 Hz. The springs are attached to the plate at the pre-generated nodal locations using the small magnets located at the top the assembly. One hundred realizations of the oscillators are created (by hanging the oscillators at random locations) and tested individually in this experiment. We used a shaker to act as an im-
pulse hammer. It generated impulses at a pulse rate of 20 s and a pulse width of 0.01 s. As seen in Fig. 3(a), six accelerometers are used as the response sensors.

The mean of the amplitude from experiment and the proposed reduced diagonal Wishart matrix approach are compared in Fig. 4 for the driving-point-FRF and a cross FRF. The corresponding relative standard deviations are shown in Fig. 5. We obtained the relative standard deviation by dividing the standard deviation with the respective mean values. We have used 2000 samples in the Monte Carlo Simulations. The first 600 modes are used in calculating the frequency response functions. This requires the simulation of a $600 \times 600$ Wishart random matrix only. Note that the dimension of full random matrix with reliable first 600 modes would be very large. A modal damping factor of 0.7% is assumed for all of the modes. A constant damping factor for all the modes is an assumption. Ideally one should identify damping using advanced methods. It is however a widely established practice to treat damping in a simple manner such as a constant modal damping factor as considered here.

Recall that there are four key parameters needed to implement the random matrix approach. They are respectively the mean and dispersion parameter of the mass and stiffness matrices. The mean system is considered to be the cantilever plate shown in Fig. 3. The mean mass and stiffness matrices are obtained using the standard finite element approach. The mean damping matrix for the experimental system is not obtained explicitly as constant modal damping factors are used. All 100 realizations of the plate and oscillators were individually simulated. The dispersion parameters of the mass and stiffness matrices are obtained as $d_M = 0.0286$ and $d_K = 0.0017$. The only uncertainty related information used in the random matrix approach are the values of $d_M$ and $d_K$. The explicit information regarding the spatial locations of the attached oscillators including their stiffness and mass properties are not used in fitting the Wishart matrices. This is aimed to depict a realistic situation when the detailed information regarding uncertainties in a complex engineering system is not available to the analyst.

In Figs. 4 and 5 observe that both means and standard deviations obtained from the proposed reduced diagonal Wishart matrix

\begin{figure}[h]

\caption{A cross FRF}
\end{subfigure}
\caption{Comparison of relative standard deviation of the amplitude obtained using the experiment and the proposed reduced diagonal Wishart matrix approach for the plate with randomly attached oscillators.}
\end{figure}
approach agree qualitatively with the experimental results. For the two FRFs shown here, the agreement is particularly good above 1 kHz frequency range. The discrepancies, especially in the low frequency regions, are perhaps due to incorrect values of the damping factors. The agreement with this limited experimental results shows that the proposed reduced computational approach might be applicable for uncertainty quantification of real-life dynamical systems. Next we integrate this approach with a general purpose finite element software.

6. Application and integration with general purpose finite element software

To illustrate the application of the method developed in the paper, we consider a simplified model of an aircraft wing. The model is shown in Fig. 6. The modeling is done using the ANSYS™[24] finite element software. The wing is of uniform configuration along its length and its cross-sectional area is defined by a straight-line and a spline. It is firmly attached to the body of the aircraft at one end and hangs freely at the other. The width and length of the wing are 1.5 m and 20.0 m, respectively. The height of the aerofoil section is 0.3 m. The wing is made of low density polyethylene with a Young’s modulus of 262 MPa, Poisson’s ratio of 0.3 and a density of 888.10 kg/m³. In this analysis, 8-noded brick element (SOLID45) is used with global element size as 0.10 m. The total degrees-of-freedom of the system turned out to be 5907. It is assumed that the wing is excited by an unit harmonic excitation at the point shown in Fig. 6 (aimed to simulate excitation coming from the engine) and we are interested in the dynamic response of the tip of the leading edge of the wing. For the finite element model we obtain the input node number 407 and the output node number 96 corresponding to these two points. A constant 2% modal damping factor is assumed for all modes.

We are interested in frequency response of this system up to 1.0 kHz. The system has about 47 modes within this frequency range. Consequently we have used $m = 50$ in our calculations. Four selected modes are shown in Fig. 7 for illustration. For the system uncertainty, four values of the dispersion parameters, namely $\delta_M$, $\delta_K = 0.1, 0.2, 0.3$ and 0.4, are considered for the mass and the stiffness matrices. The method outlined in the previous section is used with 10,000 samples in the Monte Carlo Simulation.

Fig. 6. The finite element (FE) model of an aircraft wing (5907 degrees-of-freedom). The width is 1.5 m, length is 20.0 m and the height of the aerofoil section is 0.3 m. The material properties are: Young’s modulus 262 Mpa, Poisson’s ratio 0.3 and mass density 888.10 kg/m³. Input node number: 407 and the output node number 96. A 2% modal damping factor is assumed for all modes.

Fig. 7. Four selected mode shapes of the baseline model of the wing.
The baseline and mean of the amplitude of the driving-point FRF obtained using the proposed reduced approach for the four sets of dispersion parameters are shown in Fig. 8(a). Except in the lower frequency range, the ensemble means of the response amplitude obtained for the four sets of dispersion parameters do not follow the deterministic result closely. However, the ensemble means for different sets of dispersion parameters are very close to each other. Unlike the driving-point FRF, the ensemble mean of the response amplitude of the cross FRF shown in Fig. 8(b) follows the deterministic result relatively closely and also the means obtained for different sets of dispersion parameters are very close to each other.

The standard deviations of the amplitude of the FRFs obtained using the proposed reduced approach for the four sets of dispersion parameters are shown in Fig. 9. As expected, the lower values of \( \delta_k \) and \( \delta_M \) correspond to lower values of standard deviations and vice versa. The fluctuations in the standard deviations are larger in the high frequency rage compared to low frequency range. This study shows that, due to the non-intrusive nature, the proposed reduced method can be easily integrated with a commercially available general purpose finite element software for uncertainty quantification.

7. Summary and conclusions

The discretized equation of motion of linear stochastic dynamical systems is characterized by random mass, stiffness and damping matrices. The possibility of using a single reduced Wishart random matrix model for the system is investigated in the paper. Closed-form analytical expressions of the parameters of the reduced Wishart random matrix have been given. The new approach requires the baseline mass and stiffness matrices and dispersion parameters associated with these matrices. The main novelty of the proposed approach compared to existing random matrix approaches are (a) it only requires the simulation of one random matrix, and (b) the size of the random matrix to be simulated can be significantly smaller compared to the original system matrices. The proposed approach is however limited to systems with proportional damping only. The core computational cost of the proposed Monte Carlo simulation based method consists of (a) the genera-
tions of a single Wishart random matrix of dimension equaling to the number of modes retained in the study, and (b) the solution of a standard random eigenvalue problem of reduced dimension. This computational efficiency is arising from the fact that the number of vibration modes is generally much smaller than the dimension of the system random matrices.

The proposed simulation approach is applied to the forced vibration problem of a plate with stochastically inhomogeneous properties. Numerical results shown that it is possible to predict the variation of the dynamic response using the new approach with an acceptable accuracy. The feasibility of adopting a single reduced Wishart random matrix model to quantify uncertainty in structural dynamical systems has also been investigated using experimental data. In particular, uncertainty in a vibrating plate due to disorderly attached spring-mass oscillators with random natural frequencies is considered. One hundred nominally identical dynamical systems were physically generated and individually tested in a laboratory setup. The uncertainty in the response of the main structure primarily emerges from the random attachment configurations of the subsystems having random natural frequencies. Two of the measured frequency response functions were used to validate the applicability of the proposed approach. To demonstrate the generality of the method, it has been integrated within the ANSYS finite element software. As an illustration, a model of the wing of an aircraft with uncertainty is considered. The new reduced approach opens up the possibility of performing uncertainty quantification on real-life large structural dynamic systems in a computationally efficient manner.
