Electron capture times in a quantum well (QW) structure with finite electron density are calculated for electron-electron (e-e) and electron-polar optic phonon (e-pop) scattering. We find that the capture time oscillates as function of the QW width for both processes with the same period, but with very different amplitudes. For an electron density of 10^{11} cm^{-2} the e-e capture time is 10^5 times larger than the e-pop capture time except for QW widths near the resonance minima, where it is only 2–3 times larger. With increasing density the e-e capture time decreases and near the resonance becomes smaller than the e-pop capture time. Our e-e capture times are three orders larger than the results of Blom et al. [Appl. Phys. Lett. 62, 1490 (1993)]. The role of the e-e capture in QW lasers is therefore readdressed. © 1996 American Institute of Physics.

The electron capture in a quantum well plays an important role in optimizing the performance of separate confinement heterostructure quantum well (SCHQW) lasers. Quantum calculations of polar optic phonon (pop) emission induced capture in GaAs QW predicted oscillations of the capture time versus the QW width, which have been observed. The minima of the oscillations provide the optimum well and barrier width for an optimized capture. At high electron densities the electron-electron (e-e) scattering induced capture is expected to be important. Blom et al. predicted that the e-e capture time in a GaAs QW with electron density of 10^{11} cm^{-2} oscillates with nearly the same amplitude and period as the e-pop capture time. Away from the oscillation minima the e-pop capture was weak and the e-e capture was expected to increase the threshold current in the SCHQW laser via excess carrier heating in the QW.

In this letter the e-e and e-pop scattering induced capture times are recalculated for the same SCHQW as in Ref. 3. We find that for an electron density of 10^{11} cm^{-2} the e-e capture time is 10^3–10^4 times larger than for QW widths near the resonance minima, where it is only 2–3 times larger. For densities above ~5 \times 10^{11} cm^{-2} the resonant e-e capture time is smaller than the e-pop capture time. This optimizes the capture. The e-e capture is found to be too weak to cause an excess carrier heating which is in contrast to Ref. 3.

We analyze the Al_xGa_{1-x}As/GaAs/Al_yGa_{1-y}As QW with 500 Å Al_xGa_{1-x}As barriers, embedded between two thick AlAs layers. When two electrons in subbands \( i,j \) with wave vectors \( \mathbf{k} \) and \( \mathbf{k}_0 \) are scattered to subbands \( m,n \) with wave vectors \( \mathbf{k}' \) and \( \mathbf{k}'_0 \), the e-e scattering rate of an electron with wave vector \( \mathbf{k} \) from subband \( i \) to subband \( m \) reads:

\[
\lambda_{im}(\mathbf{k}) = \frac{1}{N_S g} \sum_{\mathbf{k}_0} f_j(\mathbf{k}_0) \lambda_{ijmn}(g),
\]

where \( g = |\mathbf{k} - \mathbf{k}_0| \).

\[\lambda_{ijmn}(g) = \frac{N_S m^* e^4}{16 \pi \hbar^3 \kappa^2} \frac{2 \pi}{g^2 e'(q)} \int_0^{2\pi} d\theta \frac{F_{ijmn}(q)}{q^2 e'(q)}.
\]

\[q = \frac{1}{2} \left( 2g^2 + \frac{4m^*}{\hbar^2} E_S - 2g \left( g^2 + \frac{4m^*}{\hbar^2} E_S \right)^{1/2} \cos \theta \right)^{1/2},
\]

\[F_{ijmn}(q) = \int_{-\infty}^{\infty} dz \int_{-\infty}^{\infty} dz_0 \chi_i(z) \chi_j(z_0)
\times e^{-q|z-z_0|} \chi_m(z) \chi_n(z_0).
\]

\[E_S = E_i + E_j - E_m - E_n, \]

\( N_S = 10^{11} \text{ cm}^{-2} \), \( e(q) = 1 + (q_S/q) F_{1111}(q) f_i(\mathbf{k}_0 = 0) \) is the static screening function due to the electrons in the lowest subband, \( F_{1111}(q) \) is the Fermi function taken at temperature 8 K and for an electron density \( N_S = 10^{11} \text{ cm}^{-2} \), \( q_S = e^2 m^*/(2 \pi \hbar^2) \).

Full circles in Fig. 1 show \( \tau_{e-e} \) versus the QW width for \( f_i(\mathbf{k}) \) taken as a constant distribution up to 36.8 meV above the AlGaAs barrier, which models the injected “barrier” distribution after a phonon cooling. In the inset our calculation is compared with the result of Ref. 3. Both curves oscillate with the QW width and reach a resonant minimum, whenever a new bound state merges into the QW (the shift of our resonances to slightly lower QW widths is due to differ-
ent effective masses in GaAs, AlGaAs and AlAs, which we considered when we calculated the electron wave functions. However, our $\tau_{e-e}$ is two-to-three orders larger. The difference of a factor of 4 is due to the missing factor of 1/4 in the e-e scattering rate of Ref. 3 (see Ref. 4 for details), but the remaining difference is still huge.

In order to provide insight we consider the QW width $w = 49 \text{ Å}$. To demonstrate how the form factor [see Fig. 2(a)] affects the e-e scattering rate, we compare in Fig. 3(a) $\lambda_{ijmn}(g)$ as obtained using $F_{ijmn}(q)$, shown in Fig. 2(a), with $\lambda_{ijmn}(g)$ obtained with $F_{ijmn} = 1$. The latter is between $10^{12} \text{ s}^{-1}$ and $4 \times 10^{12} \text{ s}^{-1}$ for all capture transitions and its dependence on $i,j,m,n$ is manifested through $E_5$. Figure 3(a) shows a quite different behavior and the relative importance of the individual transitions is determined by the form factors [Fig. 2(a)]. The individual capture times are at least two orders larger than the subpicosecond capture times shown in Fig. 3(b). Subpicosecond e-e scattering is characteristic for intrasubband transitions as illustrated in Fig. 3 for $\lambda_{1111}(g)$. The form factor $F_{1111}$ reduces $\lambda_{1111}(g)$ insignificantly and $\lambda_{1111}(g)$ values are close to similar calculations of Ref. 6. We believe that Ref. 3 predicts much smaller e-e capture times due to a numerical error. It is straightforward to verify Fig. 3(b) quantitatively, because formula (2) is reduced to a single-integral for $F_{ijmn} = 1$. As for the form factors, we can reproduce those published in Ref. 3. It can be seen that the results in Fig. 3(a) have correct order of magnitude, since they follow from Figs. 3(b) and 2(a).

The e-pop scattering rate of an electron with wave vector $k$ from subband $i$ to subband $m$ reads (for emission)\(^7\)

$$\lambda_{im}(k) = \frac{e^2 \alpha m^*}{8 \pi \hbar^2} \left| \frac{1}{\kappa_\infty} - \frac{1}{\kappa} \right| \int_0^{2\pi} d\theta \frac{F_{iimm}(q)}{q \epsilon(q)},$$

$$q = \left[ 2k^2 + \frac{2m^*}{\hbar^2} P - 2k \left( k^2 + \frac{2m^*}{\hbar^2} P \right) \cos \theta \right]^{1/2},$$

where $P = E_i - E_m - \hbar \omega$, $\hbar \omega$ is the pop energy and $\kappa_\infty$ is the high frequency permittivity. We calculate the e-pop scattering induced capture time $\tau_{e-pop}$ by averaging Eq. (5) as discussed for $\tau_{e-e}$. Figure 4 compares $\tau_{e-pop}$ with $\tau_{e-e}$ parameters and the constant distribution $f_i(k)$ from Fig. 1. The $\tau_{e-pop}$ data shown by empty circles are calculated using the same static screening $\epsilon(q)$ as for the e-e scattering, empty squares show $\tau_{e-pop}$ for $\epsilon(q) = 1$. A calculation with dynamic screening will give results between these two extreme cases. We conclude that $\tau_{e-e}$ is one-to-three orders larger than $\tau_{e-pop}$ except for QW widths near the resonance.

FIG. 1. E-e capture time $\tau_{e-e}$ vs the QW thickness for $N_e = 10^{11} \text{ cm}^{-2}$. In the inset these results are compared with the data (crosses) from Ref. 3.

FIG. 2. (a) Square of the e-e scattering form factor $F_{ijmn}(q)$ vs the wave vector $q$ for a QW with thickness $w = 49 \text{ Å}$. The indices $i,j$ and $m,n$ label the initial and final states, respectively. States 1,2 are bound in the QW, states 3,4,...,9 have subband energies above the AlGaAs barrier. Except for the transition 11–11 all other transitions are the e-e capture transitions. (b) The e-pop scattering form factors $F_{ijmn}(q)$ are shown for comparison.

FIG. 3. E-e scattering rate $\lambda_{ijmn}$ vs the wave vector $g$. (a) Calculation with form factors from Fig. 2(a). (b) Calculation with $F_{ijmn} = 1$. 

Kálna, Moško, and Peeters

minima. This conclusion differs from previous analysis which predicts nearly the same oscillation amplitude in both cases. Reference 3 predicts that in the SCHQW lasers with a QW width below 40 Å the e-e capture causes significant excess carrier heating in the QW. Figure 4 does not support this conclusion, because the e-e capture is negligible.

Now we assess the dependence of both capture times on the electron density $N_s$. For $N_s \geq 10^{11}$ cm$^{-2}$ and temperature 8 K the static screening $\epsilon(q)$ is independent on $N_s$, because $f_1(0)=1$. Therefore, the $\tau_{\text{e-pop}}$ values in Fig. 4 would be the same also for higher $N_s$ and the $\tau_{\text{e-e}}$ values would decrease approximately like $N_s^{-1}$ for each QW width. In Fig. 4 we show $\tau_{\text{e-e}}$ for $N_s = 2.8 \times 10^{11}$ cm$^{-2}$, $5 \times 10^{11}$ cm$^{-2}$ and $10^{12}$ cm$^{-2}$ at QW widths of 43 Å and 46 Å. At 43 Å $\tau_{\text{e-e}}$ is much larger than $\tau_{\text{e-pop}}$ even for $N_s = 10^{12}$ cm$^{-2}$ due to the absence of resonance. At 46 Å, when the first excited subband merges into the QW, $\tau_{\text{e-e}}$ resonantly decreases about 500 times and becomes smaller than $\tau_{\text{e-pop}}$ when $N_s = 5 \times 10^{11}$ cm$^{-2}$. When $N_s = 10^{12}$ cm$^{-2}$, the total capture time $\tau_{\text{e-e}} + \tau_{\text{e-pop}}/\tau_{\text{e-e}} = 3.8$ ps for the unscreened e-pop capture ($\tau_{\text{e-pop}} = 11$ ps) and 4.3 ps for the screened e-pop capture ($\tau_{\text{e-pop}} = 18$ ps). Thus, compared to the case $\tau_{\text{e-e}} = 0$ the capture efficiency of the QW with the optimized (resonant) width can be improved with a factor $2.9 - 4.2$ by increasing $N_s$ to $10^{12}$ cm$^{-2}$. For $N_s > 10^{12}$ cm$^{-2}$ the capture time is expected to increase because the electrons interact with a coupled system of electrons and phonons.

The $\tau_{\text{e-pop}}$ curve in Fig. 4 does not show a resonant drop for QW widths 46 Å and 88 Å, because the “barrier” electrons occupy the states below the threshold for pop emission and cannot be scattered into the subband which is in resonance with the top of the QW. A further increase of the QW width shifts the resonant subband deeper into the QW and the e-pop scattering into this subband smoothly increases. Figure 5 compares the unscreened e-pop scattering rates obtained using $F_{\text{iimm}}$ from Fig. 2(b) with the rates obtained with $F_{\text{iimm}} = 1$. The individual e-pop capture rates in Fig. 5(a) are governed by the relevant form factors, while for $F_{\text{iimm}} = 1$ [Fig. 5(b)] one only finds a simple dependence on $P$. Compared to the e-e scattering rates in Fig. 3(a) the corresponding rates in Fig. 5(a) are systematically higher, because the e-e capture rate Eq. (5) depends on $F_{\text{iimm}}$ linearly while the e-e scattering rate Eq. (2) depends on $F_{\text{iimm}}$ quadratically. This fact makes the e-e capture less effective than the e-pop capture except for high electron densities.

In summary, the e-e and e-pop capture times in the SCHQW capture oscillate with the same period, but with very different amplitude. The e-e capture time is much larger than the e-pop capture time except for the QW widths near resonances, where it can be even smaller for electron densities close to $10^{12}$ cm$^{-2}$ which leads to an improved capture efficiency of the QW. However, an inefficient e-pop capture in the SCHQW laser should not lead to excess carrier heating due to e-e induced capture, because away from the resonance it is still much stronger than the e-e capture.
